Traumatic brain injury in dogs and cats can occur due to a variety of causes including motor vehicle accidents, falls from a height, crush injuries, or attacks by other animals. This event secondary to a serious accident can be terrifying for owners and is a veterinary emergency for the injured patient. Initial patient assessment and rapid initiation of appropriate treatment measures are critical to maximize the chance for a successful outcome. Appropriate guidelines for veterinary patients are somewhat limited and, therefore, often based on results of human trauma studies, experimental investigations, and clinical experience.

**PATIENT ASSESSMENT**

**MODIFIED GLASGOW COMA SCALE (MGCS)**

One quantitative measure shown to be associated with survival in dogs with traumatic brain injury is the Modified Glasgow Coma Scale. This scale has been shown to predict the probability of survival in the first 48 hours in patients with traumatic brain injury. It is therefore most useful for initial patient assessment; however, it can also be used as an objective way to monitor progression of neurological signs on a serial monitoring basis. The MGCS provides a score that addresses the three domains listed below. A score of 1-6 is assigned to each category; the final score ranges from 3–18, with lower scores indicating more severe neurologic deficits.

1. **Level of Consciousness**
   - Alert and responsive: normal responses to sensory stimuli
   - Obtunded: slow/inappropriate responses to sensory stimuli
   - Stuporous: unresponsive except to noxious stimuli
   - Comatose: completely unresponsive to repeated noxious stimulation

2. **Pupil response to light and other brainstem reflexes** (palpebral, corneal, gag)

3. **Posture and motor activity (1-6)**
   - Ambulatory vs. non-ambulatory status
   - Abnormal postures
     - Decerebrate rigidity = stupor/coma, rigid extension of all 4 limbs, opisthotonus (brainstem lesion)
     - Decerebellate rigidity = conscious/mentally alert, rigid extension of thoracic limbs, flexion of pelvic limbs, opisthotonus (cerebellar lesion)

In 38 dogs with head trauma, the MGCS predicted the probability of survival in the first 48 hours. The graph below illustrates there is a 50% probability of survival in a patient with a score of 8; patients with scores higher than 8 have a higher probability of survival compared to patients with lower scores.
DIAGNOSTICS:
Complete bloodwork (an initial PCV/TS, blood glucose, and electrolytes followed by a complete cbc/chemistry panel) as well as assessment of the abdomen and chest for signs of trauma (if indicated) should be obtained. Radiographs of the head can be taken to screen for the presence of skull fractures. Imaging of the brain in head trauma patients is via CT or MRI examination; these advanced imaging tests provide assessment of both skull and brain damage. In a recent study of 18 dogs with acute head trauma, dogs with parenchymal brain injuries affecting the caudal fossa (brainstem/cerebellum) alone or affecting both the rostral (forebrain) and caudal fossa typically had poorer outcomes.3 If a patient’s neurological status continues to decline despite aggressive medical treatment, then evaluation of the extent of brain damage via CT or MRI exam and consultation with a veterinary neurologist is indicated.

THERAPY:
The goals of treatment in traumatic brain injury include reducing intracranial pressure, maintaining blood pressure, and ensuring proper ventilation. Hyperosmolar therapy reduces brain edema. Mannitol is a hyperosmolar osmotic diuretic which is considered the first line treatment for reducing intracranial pressure; administration of mannitol (0.5-2 grams/kg as an IV bolus over 20minutes q6-8 hours) has been shown to have a beneficial effect on neurological outcome in human and veterinary patients with brain injury. Hypertonic saline (3-5ml/kg) is another hyperosmolar solution with effects similar to mannitol which can be used to reduce intracranial pressure and rapidly provide intravascular volume expansion. Other important steps in managing trauma patients include intravenous fluid therapy to prevent hypotension, placing patients in an oxygen-rich environment to prevent hypoxia, and close monitoring of ventilation to prevent hypercarbia. Analgesic care should be given as needed with opioids or other reversible medications. If there is a risk for infection, antibiotic therapy should be provided to reduce the risk of an abscess from developing. Importantly, glucocorticoids are contra-indicated and should not be given to patients with brain injury; administration of steroids is associated with worse outcomes in human adults with head trauma. A helpful clinical practice review article from the Journal of Veterinary Emergency and Critical detailing medical management recommendations for patients with traumatic brain in is provided below in the article references.4

PROGNOSIS:
There is scarce available information that is predictive of prognosis in veterinary medicine for patients with traumatic brain injury. However, many patients can recover if systemic and neurological abnormalities are identified and treated early. Dogs and cats have an extraordinary ability to compensate and improve after sustaining brain damage. Longterm effects such as post-traumatic epilepsy are reported to occur in a small percentage of patients with head trauma; in one retrospective study of dogs with epilepsy, 15% of dogs had a history of prior head injury.5 Ultimately, patient response and degree of improvement to treatment over time ultimately determines the prognostic outcome.
